RESULT AND DISCUSSION

CHAPTER IV

Result And Discussion

The electrical transport properties of amorphous semi-conducting Se-Te-Sb system, are discussed here. Amorphous structure of the material, under study, is confirmed from the X-ray diffraction pattern, which consist of broad rings, vanishing rapidly with increasing angle, without any evidence of spots or sharp rings, which would indicate some degree of crystallinity. The X-ray diffraction pattern show diffused rings. This means that Se-Te-Sb is amorphous in nature.

Current voltage characteristics are measured for sample $Se_{70}Te_{30}$, and $Se_{70}Te_{30-x}Sb_x$ (where $X=1,3,5,7,9\%$ atomic weight). The same characteristics of the sample $Se_{70}-Te_{25}-Sb_5$ with different thickness (0.130, 0.144, 0.180, 0.234, 0.300 cm.) were also studied.

The current voltage characteristics at different compositions are shown in [Figure 3-11]. The I-V curves are usually symmetric in nature, when applied field is very low, it appears almost across the contacts and the interelectrode bulk field is also very low, and therefore, the current in the circuit is very less, i.e. current in (μA) is observed. At this low current value, the resistance of the material is very high. This is the off state regime. The low current obtained may be due to the thermally generated carriers from the defect states, existing in the bulk of the material. Therefore, the curves at low field are ohmic in nature.

When the applied field is increased, the current density becomes very high, at the threshold field [250] volts. At this point the resistance of the sample becomes low, this is the ON state of the material. High current at ON state is due to the free charges and released charges from the traps. Normally the negative charges and positive charges are equal in magnitude. At high field the dense electron-hole Plasma would be injected from each side of the electrode. The ON state would be maintained as long as injection rate is equal to recombination rate (4.1). If the injection rate becomes smaller than recombination rate then the ON state will not be maintained, because the holding current will decrease in the circuit (4.2). At this stage, the material goes from nonconducting state to conducting state. It is the ON state. Such mechanism has been proposed by several authors (4.3, 4.4). Some authors have involved, mechanism of carrier multiplication in various forms (4.5, 4.6).

Here we would like to discuss the non-linear I-V behaviour on the basis of charge defect states introduced by Kastner and Hudgens [4.2]. They proposed that in amorphous semiconductors the lower energy defect states are positively charged threefold coordinate C_3^+ and negatively charged One-fold coordinate C_1^- chalcogen atoms. When an electric field is applied to an amorphous semiconductor, electrons and holes are injected from the cathode and anode into the material.

Initially the injected electrons and holes are held up at the electrodes, as there is no internal electric field. At the cathode the electrons are trapped by C_3^+ (donors) centres which transform to C_3° neutral centres. At the cathode the C_1^- centres capture the holes and transform to C_3° neutral centres. The electrons are captured at faster rate than holes, because of the mobility of the electrons is higher than that of holes. This will result in creating a higher concentration of C_1^- centres as compared to that of C_3^+ centres. Thus at the anode a high field exists, and holes drift towards the cathode, where they are captured by the C_3° neutral centres, thus creating C_3° centres at the anode. This increases the field at the cathode and thus electrons drift from the cathode towards the anode, where they are again captured by the C_3° centres and C_1^- are formed.

The current voltage characteristics of $Se_{70}-Te_{25}-Sb_5$ for different sample thicknesses are shown in figure (3.12). The nature of curves for different thicknesses of the material is the same and it can be explained by the same mechanism given above. The only difference, we observed that as the thickness increases the current in the circuit decreases for the same field value it may be explained that in a thin sample the voltage required to inject the required amount of charges for building up an internal field is less because of small distance between the electrode and smaller value of resistance of the sample. While in the thick sample, the voltage required to inject the same density of charges,

for building up the internal field is large because of the large distance between electrodes and greater value of resistance of the thick sample. Therefore, as the thickness of the sample decreases, the conductivity of the sample increases.

D.C. Conductivity

The experimental conductivity data of six samples of the system $\text{Se}_{70}\text{-Te}_{30}\text{-Sb}_x$ (where $x=1,3,5,7,9\%$ atomic weight) is listed in table (4.1). The conductivity is represented by Mott's equation

$$\sigma = C \exp.\left(-\frac{E_{\sigma}^*}{KT}\right) \quad (4.1)$$

the value of activation energies E_{σ}^* obtained from the curves drawn between $\log \sigma$ against $1/T$ and the preexponential factor C , are listed in table (4.1). It is observed that conductivity increases with increase in antimony concentration in the samples. For $\text{Se}_{70}\text{-Te}_{30}$, activation energy is 0.6341 eV and increases to 0.9702 eV. for $\text{Se}_{70}\text{-Te}_{23}\text{-Sb}_7$. It is suggested by Haisty and Krab [3] that the incorporation of Sb in Se-Te is regarded as forming mixed rings and strong covalent bonds, between the atoms in the rings. The addition of Sb leads to cross-linking between the chains promoting the formation of three dimensional net work. The addition

of Sb weakens the bonds in rings which will influence the band structure of the material and hence electrical properties. Therefore, we must get increase in conductivity with increase in Sb concentration. Such type of behaviour is observed for our system. It is found that, with increase Sb concentration, the conductivity increases up to $Se_{70}-Te_{23}-Sb_7$.

But for the sample $Se_{70}-Te_{21}-Sb_9$ it is found that activation energy decreases. This type of behaviour may be due to some changes in the bulk of the material. It may be due to the higher concentration of antimony. The material may be converted from amorphous to crystalline phase. The X-ray diffraction study [Fig. 3.7] of the same sample also support to the above nature. In X-ray diffraction pattern, we get some peaks which indicates the crystallinity of the sample. The I-V characteristics study also supports to above observed fact, for sample $Se_{70}-Te_{21}-Sb_9$ in which current decreases.

We can also explain the above Result with the help of, sample (Si-H) with Al.

The influence of Aluminium upon electronic transport of amorphous (Si-H) has been reported by Fortuna and Marshall^{4.7}. They have observed that the activation energy decreases as percentage of Aluminium in the sample increases, indicating thereby that the conductivity of the sample

increases. They have explained this on the basis of formation of Aluminium islands in the semiconducting medium. The conduction takes place between two islands, when the carriers move in the medium. The material does not become completely metallic but the current value increases because of increase in Aluminium content and conductivity increases. For our sample $\text{Se}_{70}\text{Te}_{30}$ the conductivity increases as the percentage of antimony increases in the sample. But at higher concentration of Sb the amorphous material may be slowly converted in to crystalline form, as a result thereby decrease of conductivity value.

Fig. (3.14) shows variation of room temperature conductivity, with variation of antimony concentration. It is seen from figure that, conductivity increases with increasing antimony concentration.

Fig.(3.15) shows, variation of pre-exponential factor 'C' against concentration of antimony. From this curve we find that the pre-exponential factor 'C' is not constant but depends upon glass composition. The value of 'C' lies between (-3.2×10^{-7} to 3.83×10^{-6}) for different concentrations of antimony in Se-Te. Mott and Davis (4) argued that, there is no definite correlation between the intercept 'C' and activation energy E_g^* of amorphous semiconductors. However the present investigations show that 'C' decreases

with increase in activation energy. According to Mott and Davis the intercept 'C' is related to density of localized state. As 'C' decreases the density of localized states increases. Thus observed in 'C' with composition probably suggests the formation of glass composition with higher degree of disorder. This behaviour is also explained by Majid et al(4).

Fig.(3.16) shows variation of room temperature conductivity with activation energy. It has been observed that the conductivity increases with increase in activation energy and high concentration of Sb with decrease in activation energy, which is in agreement with observations given by Majid(4), for the system $(As_2-Se)_{1-x}(Ti_2Se)_x$.

The variation of E_g^* with concentration X and E_g^* with 'C' is shown in figure (3.17,3.18). Figure (3.17) shows that as antimony concentration increases in the sample, the activation energy increases, it means, the conductivity of the sample decreases as the antimony concentration increases.

Fig.(3.22-) in sample $Se_{70}Te_{23}Sb_7$ shows variation of conductivity with field strength, at different temperatures. It is observed that, the conductivity increases with increase in field strength, at room temperature. This increase in conductivity at room temperature is found to depend, on antimony concentration in Se-Te system. As antimony concentration is increased, less increase in conductivity is found. It is found that, above $60^\circ C$, the conductivity becomes independent of field strength.

At room temperature the charge carriers are accelerated, due to applied field. As field is increased, more and more charges reach to anode, resulting increase in current. At high temperature the number of charge carriers are more as compared to room temperature, but the effect of field is not predominant.

Thermo-e.m.f.

Figure[3.21] shows variation of e.m.f. with temperature difference. It shows that the thermo e.m.f. varies linearly with temperature difference. As we get positive thermo e.m.f. for the sample, the charge carriers are holes, and the material is p-type in nature.

The variation of thermoelectric power with $\frac{1}{T}/^{\circ}\text{K}$ is shown in fig.(3.22). It is observed that the thermoelectric power varies linearly in all the samples. There is increase in thermoelectric power with increase of antimony in Se-Te.

The thermoelectric power equation given by Fritzsche[6]

$$S = \frac{K}{e} \left[\frac{E_s^*}{KT} + A \right] \quad (4.2)$$

is used to calculate the activation energy. For most of the chalcogenide glasses $A=1$. The activation energy calculated from the curves comes out to be 0.4951 eV. for $\text{Se}_{70}\text{-Te}_{30}$ and increases to 0.8184 eV. for $\text{Se}_{70}\text{-Te}_{23}\text{-Sb}_7$.

The activation energy increases as the percentage of antimony in Se-Te system increases. The difference in activation energy, calculated from the conductivity and thermoelectric power measurement is

$$(E_Q = E_{\sigma}^* - E_S^*) \approx 0.1 \text{ ev.}$$

The values E_S^* and E_Q are listed in table no.4.1. Several models have been proposed to explain the features found experimentally for the difference in activation energy, calculated from conductivity and thermoelectric power. For chalcogenide P.Nagels[7] proposed ambipolar transport. This difference in activation energy (E_Q), could represent an activation energy in the mobility, $\mu(T)$ which enters the expression for σ i.e.

$$\sigma = \int_{-\infty}^{+\infty} g(E) f(E) e \mu(E) dE \quad (4.3)$$

But not for S. In that case, conduction could be due to small-polaron hopping. However the conductivity data appear to require sufficiently large mobilities, that this mechanism is highly unlikely [8]. At the present time, none of the three standard transport properties σ , S, and R_H can be considered to be understood. It is clear that σ can be modulated over many orders of magnitude both by n-type and p-type doping. Overhof and Beyer[9] have reported difference between activation energies as 0.1 eV to 0.2

eV. for chalcogenide glasses, and α -Si-H. They have also discussed various transport modes considering the transport properties of both chalcogenide and α -Si-H, simultaneously. They have defined $Q(T)$ by the following relation

$$Q(T) = \ln \sigma(T) + q/k S(T) \quad (4.4)$$

with $q = -|e|\hbar^2$ for electron and
 $q = +|e|\hbar^2$ for holes.

They have also shown that both for silicon and chalcogenide, the $Q(T)$ curves are generally well represented by

$$Q(T) = Q_0 - E/KT \quad (4.5)$$

Following Overhof and Bayer, we have plotted the graph of $Q(T)$ against T^{-1}/K for our system as shown in fig. [3.23]. The slope of curve yields Q_0 values which are presented in table (4.1). Many attempts have been made to explain the non-zero value of E_Q [9]. When transport takes place in the extended states, above the mobility edge,

$$Q(T) = \ln \left(\sigma_{\min} \bar{\Omega}^1 \text{ cm}^{-1} \right) + 1 \quad (4.6)$$

The value of E_Q obtained from above equation are in agreement with value reported in the literature [10].

The non-zero slope of $Q(T)$ is due to long range static potential that modulates the energy of mobility edge in space [9]. The origin of this potential could be electro-

static potential of charged centres which are probably not homogeneously distributed in space than random distribution. In this case variation of E_Q with preparation and doping level had to be attributed to long range potential. It has been reported that, in highly doped or more disordered samples E_Q may as large as 0.25 eV, while for undoped sample $E_Q = 0.05$ eV [11].

The plot of $\ln \sigma$ against S is shown in fig.[3.24]. The slope of which enables to calculate σ_0 . It seems to us that further work both theoretical and experimental is necessary to determine σ_0 .

The conductivity is given by

$$\sigma = \sigma_0 \exp. \left[-\frac{E_c - E_F}{KT} \right] \quad (4.7)$$

at zero temperature

$$\sigma_0 = \frac{0.03 e^2}{h l_1}$$

Where l_1 is inelastic diffusion length, σ_0 is obtained from the slope of $\ln \sigma$ against S . curves the values of l_1 are listed in table 3.1.

Table NO. 4.1

Values of activation energy E_0^* , E_s^* , the intercept 'C' Room temperature conductivity $\sigma \Omega^{-1} \text{cm}^{-1}$ Energy difference, E_Q , the factor Q_0 , preexponential factor Q_0 , and inelastic diffusion length l for bulk of the sample $\text{Se}_{70}\text{-Te}_{30}\text{-Se}_{70}\text{-Te}_{30}\text{-x}$

Result and discussion of (Sb - Se - Cu)

Current voltage characteristics at different compositions are shown in fig.(3.25). The I-V curves are symmetric in nature. At low field the interelectrode bulk field is very low, and therefore current in the circuit is in (μ A) range. The resistance of the sample is very high. This is the Off state of high impedance state. The low current obtained may be due to the thermally generated carriers from the defect state, existing in the bulk of the material. Therefore, the curves at low field are ohmic in nature.

Here we would like to discuss the non-linear I-V behaviour on the basis of charge defect states, introduced by Kastner and Hudgins^{4.4}. The defect states introduced by above scientists are discussed in series $Se_{70}-Te_{30-x}Sb_x$.

The measurement of d.c. conductivity in the case of amorphous semiconductors have yielded valuable information about the transport mechanism. The majority of amorphous semiconductor at high temperature show an activated temperature dependence in accordance to the relation

$$\sigma = \sigma_0 \exp\left(-\frac{E_a^*}{kT}\right) \quad 4.8$$

Where E_a^* and σ_0 are the conductivity activation energy and pre-exponential factor respectively.

The experimental conductivity data of sample of system $Sb_{70}-Se_{25}-Cu_5$ and $Se_{70}-Se_{23}Cu_7$ are shown in fig.[3.20,21].

The value of activation energies E_0^* obtained from the curves drawn between $\log \sigma$ against $1/T$ are listed in table [3.27]. or

The observed variation of d.c. conductivity with reciprocal temperature ($\log \sigma$ Vs T^{-1}) for various bulk amorphous samples of $Sb_{70}Se_{25}C_5$ and $Sb_{70}Se_{23}C_7$ in the temperature range ($300^\circ K$ to $350^\circ K$) is shown in fig.[3.26]. It can be observed that for samples with $0.4 < x < 0.9$, the conductivity is not singly activated in the entire temperature range investigated in fact, the data are characterized by slightly curved lines with gradually increasing activation energy with increasing temperature.

It is observed that there is an decrease in conductivity with increase in Cu in the sample $Sb_{70}Se_{30-x}Cu_x$

The addition of Cu weaknes the bonds in rings which will influence the band structure of the material and hence electrical properties.

This decrease in conductivity due to increase of Cu in the sample, may be thought on the basis of Cu islands formed due to addition of Cu in to the sample. These is Islands may be of acceptar type in the amorphous field.

Figure (3.26) shows variation of room temperature conductivity σ with Cu concentration. It is seen from the figure that conductivity decreases with increasing Cu concentration.

This glass obey the $\log \sigma$ against T^{-1} °K relation over entire range of temperature. The amorphous Sb-Se-Cu system was obey this linear relation for 300°K to 340°K .

Fig. () shows variation of pre-exponential factor 'C' against concentration of Cu. From this curve we find that the pre-exponential factor 'C' is not constant but depends upon the glass composition. Mott and Davis^(4.1) argued that there is no definite correlation between the intercept C and activation energy E_{σ}^* of amorphous semiconductors. However the present investigations show that 'C' increases with decrease in activation energy. According to Mott and Davis the intercept 'C' is related to density of localized state.

Fig. () shows variation of room temperature conductivity with activation energy. It has been observed that the conductivity increases with decrease in activation energy, which is agreement with observations given by Majid⁽⁴⁾ for the system $(\text{As}_2-\text{S}_1)_{1-x}(\text{Te}_1-\text{Se}_3)_x$

The variation of E_{σ}^* with concentration X is shown in figures or Table No. 4.2.

Fig. (4.2) shows that as copper concentration increases in the sample, the activation energy is decreases in our sample Sb-Se-Cu.

Fig.(3.28) shows variation of conductivity with field strength, at different temperatures. It is observed that, the conductivity increases with increase in field strength, at room temperature. This increase in conductivity at room temperature is found to depend, on copper concentration in Sb-Se system. As copper concentration is increased, less increase in conductivity is found. It is found that, above 50 C, the conductivity becomes independent of field strength.

At room temperature the charge carriers are accelerated, due to applied field. As field is increased, more and more charges reach to anode, resulting increase in current. At high temperature the number of charge carriers are more as compared to room temperature, but the effect of field is not predominant.

Fig.(3.29) shows variation of thermo e.m.f. with temperature difference. It is found that thermo-e.m.f. varies linearly with temperature difference. The variation of thermoelectric power with $1/T$ K is shown in fig.(3.29). It is observed that the thermoelectric power varies linearly in all the samples.

There is decrease in thermoelectric power with increase in copper in Sb-Se.

The activation energy calculated from the curves comes out to be 0.5416 eV for $Sb_{70}-Se_{25}-Cu_5$ and decrease to 0.4568 eV

for $\text{Sb}_{70} - \text{Se}_{23} - \text{Cu}_7$. Therefore difference in activation energy, calculated from the conductivity and thermoelectric power measurement is $(E_a = E_\sigma^* - E_s^*) \simeq 0.1$ eV. The values of E_σ^* and E_s^* are listed in table no. (4.2). Several models have been proposed to explain the features found experimentally for the difference activation energy, calculated from conductivity and thermoelectric power. For chalcogenide P. Nagels(7) proposed ambipolar transport. This difference in activation energy (E_a), could represent an activation energy in the mobility, $\mu(T)$, which enters the expression for i.e.

$$\sigma = \int_{-\infty}^{+\infty} N(E) f(E) e \mu(E) dE \quad \dots \dots \dots 4.9$$

but not for S. In that case, conduction could be due to small-polaron hopping.
